Translog Demand PE Model of Tariff Changes

This industry-specific partial equilibrium (PE) model of trade policy quantifies the economic impacts of a tariff change on prices and quantities. Instead of CES preferences, this model uses transcendental logarithmic (translog) preferences originally proposed by Christensen, Jorgenson, and Lau (1975) and made popular in recent times by Feenstra and others. There are three sources of supply to a single market: domestic shipments (d), subject imports (s) and non-subject imports (n). The market operates under the perfect competition assumption.

The user inputs translog demand parameters, price elasticities of supply, original and new tariff rates, and initial expenditure and price data on domestic shipments, subject imports, and non-subject imports. The user can modify data inputs in the simulation by changing the values in the ORANGE-shaded lines in the notebook below. The spreadsheet will update the estimated changes in economic outcomes that are reported in the GREEN-shaded cells once the user selects “Evaluate Notebook” under “Evaluation” in the Menu above. The own- and cross-price elasticity values populate in BLUE.

This model is provided as a generic analytical tool, and the data and parameter values are fictional and illustrative. Actual data and parameter values should be supplied by the user based on the industry and market to which the model is applied. The model is the result of ongoing professional research of USITC staff and may be updated. The model is not meant to represent in any way the view of the U.S. International Trade Commission or any of its individual Commissioners. The model is posted to promote the active exchange of ideas between USITC staff and experts outside the USITC and to provide useful economic modeling tools to the public.
